Purpose: To examine the hypotheses that in glaucomatous eyes with single-hemifield damage, retinal blood flow (RBF) is significantly reduced in the retinal hemisphere corresponding with the abnormal visual hemifield and that there are significant associations among reduced retinal sensitivity (RS) in the abnormal hemifield, RBF, and structural measurements in the corresponding hemisphere.

Design: Prospective, nonrandomized, case-control study.

Participants: Thirty eyes of 30 patients with glaucoma with visual field loss confined to a single hemifield and 27 eyes of 27 controls.

Methods: Normal and glaucomatous eyes underwent spectral-domain optical coherence tomography (SD-OCT) and standard automated perimetry. Doppler SD-OCT with a double-circle scanning pattern was used to measure RBF. The RBF was derived from the recorded Doppler frequency shift and the measured angle between the beam and the vessel. Total and hemispheric RBF, retinal nerve fiber layer (RNFL), and ganglion cell complex (GCC) values were calculated. The RS values were converted to 1/Lambert. Analysis of variance and regression analyses were performed.

Main Outcome Measures: Total and hemispheric RS, RBF, RNFL, and GCC values.

Results: The total RBF (34.6±12.2 μl/minute) and venous cross-sectional area (0.039±0.009 mm²) were reduced (P < 0.001) in those with glaucoma compared with controls (46.5±10.6 μl/minute; 0.052±0.012 mm²). Mean RBF was reduced in the abnormal hemisphere compared with the opposite hemisphere (15.3±5.4 vs. 19.3±8.4 μl/minute; P = 0.004). The RNFL and GCC were thinner in the corresponding abnormal hemisphere compared with the opposite hemisphere (87.0±20.2 μm, 77.6±12.1 vs. 83.6±10.1 μm, P = 0.04). The RBF was correlated with RNFL (r = 0.41; P = 0.02) and GCC (r = 0.43; P = 0.02) but not the RS (r = 0.31; P = 0.09) in the abnormal hemisphere. The RBF (19.3±8.4 μl/minute), RNFL (103.7±20.6 μm), and GCC (83.6±10.1 μm) were reduced (P < 0.05) in the hemisphere with apparently normal visual field in glaucomatous eyes compared with the mean hemispheric values of the normal eyes (23.2±5.3 μl/minute, 124.8±9.6 μm, and 96.1±5.7 μm, respectively).

Conclusions: In glaucomatous eyes with single-hemifield damage, the RBF is significantly reduced in the hemisphere associated with the abnormal hemifield. Reduced RBF is associated with thinner RNFL and GCC in the corresponding abnormal hemisphere. Reduced RBF and RNFL and GCC loss also are observed in the perimetrically normal hemisphere of glaucomatous eyes.

Financial Disclosure(s): Proprietary or commercial disclosure may be found after the references.

Glaucoma is a multifactorial optic neuropathy, and vascular factors have been suggested to be significant contributors to the development and progression of glaucomatous optic neuropathy and visual field loss.1–7 Different studies have demonstrated that in primary open-angle glaucoma (POAG), the blood flow is diminished in the optic nerve head (ONH), retina, and choroid.8–10 The retinal ganglion cells (RGCs), retinal nerve fiber layer (RNFL), and their axons in the inner retina are supplied by the retinal circulation through the central retinal artery via the ophthalmic artery.1 Several studies have shown associations between the attenuation of retinal vessels and the severity of glaucomatous damage.11–14

Doppler spectral-domain (SD) optical coherence tomography (OCT) is a reliable and repeatable technique5,15,16 that measures the Doppler shift of reflected light due to moving blood cells and allows calculation of the total and hemispheric vein velocity and area. To compute the flow in the vessel, the technique requires measurement of the angle of the vessel relative to the scanning beam, which can be obtained using a dual circumpapillary scanning strategy. Several studies have demonstrated decreased retinal blood flow (RBF) in glaucomatous eyes compared with normal eyes using this technique.15–17

Many studies have demonstrated that eyes with visual field loss confined to a single visual hemifield have diffuse RNFL atrophy, suggesting that relatively widespread structural injury may precede localized functional loss as measured using standard automated perimetry (SAP).18–20

Longitudinal data to support this hypothesis, or the mechanism by which it occurs, are limited. We hypothesized that eyes with single-hemifield glaucomatous damage may have
significantly reduced RBF in the hemifield corresponding with the visual field loss compared with the normal hemifield and that normal hemifield has reduced RBF relative to normal controls. This study was conducted to examine the relationship among RBF, retinal sensitivity (RS), and parapapillary and macular structural measurements in glaucomatous eyes with single-hemifield damage compared with normal eyes.

Methods

Study Population

The subjects were participants of the Advanced Imaging for Glaucoma study, a prospective, nonrandomized, multicenter, longitudinal clinical trial of normal, glaucoma suspect, pre-perimetric glaucoma, and patients with perimetric open-angle glaucoma (available at: www.AIGStudy.net, accessed September 12, 2013).

Patients had perimetric glaucoma with ≥28 months of follow-up and were enrolled at Bascom Palmer Eye Institute, University of Miami; Doheny Eye Institute, University of Southern California; and the Casey Eye Institute, Oregon Health and Science University. Informed consent was obtained from all subjects using the consent forms approved by the institutional review boards of the participating institutions, which were in agreement with the provisions of Declaration of Helsinki. The study was in accordance with the Health Insurance Portability and Accountability Act of 1996 privacy and security regulations.

Inclusion criteria common to both normal and glaucoma groups consisted of reliable SAP, defined as <15% rate of fixation loss and <33% rates of false-positive and false-negative errors, spherical equivalent refractive error between −7.00 and +3.00 diopters sphere, best-corrected visual acuity of ≥20/40, age ≥40 and ≤80 years, and no history of intraocular surgery except for uncomplicated cataract extraction. Standard automated perimetry was performed in normal and glaucoma subjects using Swedish Interactive Threshold Algorithm standard 24-2 threshold test (Humphrey Field Analyzer 750 II; Carl Zeiss Meditec, Inc., Dublin, CA).

Inclusion criteria for the normal group were defined as intracocular pressure (IOP) ≤21 mmHg, normal-appearing ONH, intact neuroretinal rim and RNFL, normal SAP defined as a glaucoma hemifield test within normal limits, and pattern standard deviation within 95% confidence interval limits. Inclusion criteria for the glaucoma group consisted of glaucomatosus optic neuropathy defined as neuroretinal rim narrowing to the optic disc margin, notching, excavation, or RNFL defect, and corresponding abnormal visual field defined as abnormal glaucoma hemifield test and pattern standard deviation outside 95% normal limits. All patients with glaucoma required 1 normal visual hemifield, and the glaucomatous visual field damage had to be confined to a single hemifield. All patients had prior SAP experience and at least 1 confirmatory SAP examination for the hemifield damage. The apparently normal hemifield required having no test location worse than P < 0.01 on the pattern deviation plot. The glaucomatous hemifield required having a cluster of ≥3 contiguous test locations at P < 0.05 on the pattern deviation plot, with ≥1 test location at P < 0.01. The sensitivity of each test location was converted to the linear scale of 1/Lambert. The mean RS values in 1/Lambert were calculated in each hemifield using the average of 26/52 test locations.

Exclusion criteria common to both groups consisted of corneal or retinal pathology and prior intraocular surgery, except for uncomplicated cataract extraction or glaucoma procedures.

Subjects with ocular disease other than glaucoma or cataract, parapapillary atrophy extending to 1.7 mm from the center of the optic disc, unreliable visual field, or poor-quality RBF, ONH, or RNFL images were excluded. Patients with diabetes mellitus and systemic hypertension were included unless they were diagnosed with diabetic retinopathy or hypertensive retinopathy. Only 1 eye per subject was included.

All patients underwent a baseline examination consisting of a complete ophthalmic examination, including slit-lamp biomicroscopy, gonioscopy, Goldmann applanation tonometry, ultrasound pachymetry, dilated stereoscopic examination and photography of the optic disc, SAP, RBF measurement using Doppler SD-OCT, and RNFL and ganglion cell complex (GCC) thickness measurements using SD-OCT (RTVue-100; Optovue Inc., Fremont, CA). The IOP and blood pressure measurements were performed at the same visit. Each SD-OCT measurement was repeated twice at each session, and the best quality image, defined as having a signal strength index ≥40 with no segmentation error, was selected for the analysis. Mean ocular perfusion pressure (MOPP, in mmHg) was defined as the difference between 2/3 of mean arterial pressures and IOP. At the time of the study, each patient with glaucoma was under treatment at the discretion of the attending physician. Structural parameters included in the study were average, superior, and inferior RNFL and GCC thickness values.

Doppler Spectral-Domain Optical Coherence Tomography for Retinal Blood Flow Measurements

Doppler SD-OCT uses the Doppler technique in SD-OCT imaging and is based on the principle that moving particles, such as red blood cells inside a blood vessel, cause a Doppler frequency shift (Δf) to the light scattered based on the following equation:

\[ \Delta f = -2V_\text{r} \cos \theta \frac{\lambda_0}{\lambda} \]

where V is the velocity vector of the moving particles, θ is the angle between the scanning beam and the flow direction, n is the refractive index of the medium, and λ₀ is the center wavelength of the light. In Doppler SD-OCT, Doppler frequency shift introduces a phase shift in the spectral interference pattern that is captured by the line camera. With fast Fourier Transformation, the transform result is a complex function characterized by amplitude and phase. Structural information can be obtained via the amplitude result. The phase difference between sequential axial scans at each pixel is calculated to determine the Doppler shift. Therefore, in addition to structural imaging, Doppler SD-OCT can be used to quantify blood flow parameters. The Doppler SD-OCT device used for the RBF measurements in this study was a spectrometer-based SD-OCT (RTVue-100; Optovue Inc.). The system has a wavelength of 840 nm, an axial resolution of 5 μm, and a transverse resolution of 20 μm in tissue. The time interval between 2 sequential axial scans is 36.7 μs. The maximum measurable Doppler shift is 13.6 kHz at the phase wrapping limit of ±π radians. Radial pace shift between sequential axial scans, corresponding to a maximum measurable axial velocity component of 4.2 mm/s in the eye. The repeatability of total RBF, measured as the coefficient of variation, was 10.9% in the normal group and 14.3% in the diseased eyes, consisting of eyes with glaucoma, diabetic retinopathy, and branch retinal vein occlusion.

Doppler Image Acquisition and Processing

The pupils were dilated using 1% tropicamide and 2.5% phenylephrine eye drops. Doppler imaging was performed using a double-circular scan pattern around the optic disc. The double-circular scan pattern consists of 2 concentric circles around the ONH, with an inner ring diameter of 3.40 mm and an outer ring diameter
Multivariate regression analyses were performed to examine the hemispheric RBF in normal patients and patients with glaucoma.

An experienced grader at the Doheny Doppler SD-OCT Reading Center calculated the RBF using semiautomated software that has been described elsewhere. Blood vessels were identified on the basis of Doppler and reflectance OCT images. The determination of vein versus artery was based on the comparison between the SD-OCT images and the color fundus photographs of the disk. Vessel diameter was measured using a caliper on the cross-sectional Doppler SD-OCT images, and lumen area (πD^2/4) was subsequently calculated. The venous cross-sectional areas for all branch vessels around the optic disc were averaged to obtain the average venous cross-sectional area for the eye. The Doppler angle between the SD-OCT beam and the direction of vessel was calculated using the relative position of each vessel in the 2 concentric SD-OCT images. Eye movement had minimal effect on the calculation of Doppler angle because of the short time interval between the inner and the outer circular scans (0.16 second). Flow velocity was computed from the Doppler shift and Doppler angle, with steps to account for the effect of background retinal motion and transverse scan step size.

Veins were identified by the flow direction toward the optic disc. The volumetric blood flow rate for each pixel was calculated by multiplying the velocity by flow in the pixels over lumen cross-section. Flow measurements were averaged over each 2-second recording. For each vessel of each scan, a validation was applied on the basis of the coefficient of variation of Doppler angle.

Measurements from all valid scans were averaged. Total RBF was calculated by summing flow from all detectable veins. Since the ocular circulation is a closed circulatory system, and inflow must equal outflow in any steady-state system that obeys the law of conservation of mass, it was assumed that the blood flow in arteries and veins was equal.

### Statistical Analysis

Statistical analysis was performed using JMP software version 8.0.2 (SAS Inc., Cary, NC). The estimated sample size for an alpha level of 5% and a power of 80% was 21 to detect a 13 µl/minute difference with a standard deviation of 10% in the RBF of patients with glaucoma compared with normal controls, using the mean difference values provided by Wang et al. The distribution of data was examined using the Shapiro–Wilk W test of normality. One-way analysis of variance was used for the comparison between groups and hemispheres, and the Tukey–Kramer honestly significant difference post hoc test was applied to correct for multiple comparisons. Logistic regression analysis was conducted to examine the impact of using topical and systemic medications, vitamins, and food supplements on the total and hemispheric RBF in normal patients and patients with glaucoma. Multivariate regression analyses were performed to examine the associations between the RBF and RNFL and GCC thickness values and the RS in corresponding hemispheres and normal eyes.

### Results

Thirty glaucomatous eyes of 30 patients with glaucoma and 27 normal eyes of 27 normal subjects were included in this analysis. The RS in the apparently normal hemifield of glaucomatous eyes (28.5±2.1 dB; 774.9±322.2 I/Lambert) was significantly lower than the RS in the abnormal hemifield of glaucomatous eyes (22.5±7.1 dB, P < 0.001; 370.8±317.7 I/Lambert; P < 0.001) and was reduced compared with the mean RS of the healthy eyes but did not reach a statistically significant level (29.4±1.6 dB, P = 0.07; 935.6±327.4 I/Lambert, P = 0.07).

Table 1 describes the demographics of the study population. Normal and glaucoma groups did not have a statistically significant difference in age (65.4±9.0 vs 61.5±9.2 years; P = 0.10). The treated IOP in the glaucomatous eyes (14.2±3.9 mmHg) was similar to the untreated IOP in the normal eyes (13.9±2.3 mmHg; P = 0.74). The prevalence of diabetes mellitus and systemic antihypertensive treatment was similar between the 2 groups (Table 1). Age was not associated with total RBF (r = −0.11; P = 0.58), average RNFL thickness (r = 0.21; P = 0.27), or average GCC thickness (r = −0.06; P = 0.75) in glaucomatous eyes. The total and hemispheric RBF, venous cross-sectional area, and arteriolar cross-sectional area were significantly reduced in glaucomatous eyes compared with normal eyes, but venous blood flow velocity was similar between the 2 groups (Table 2). In the glaucoma group, systolic blood pressure was not associated with the RBF in the normal (r = 0.03; P = 0.89) or abnormal hemisphere (r = 0.19; P = 0.35). Likewise, the diastolic blood pressure was not associated with the RBF in the normal (r = −0.33; P = 0.11) or abnormal hemisphere (r = −0.003; P = 0.99). The MOPP was not associated with the RBF in the normal (r = −0.23; P = 0.25) or abnormal hemisphere (r = −0.13; P = 0.52).

The full list of the topical and systemic medications, including food supplements, has been provided in Table 3. Logistic regression analysis was conducted to examine the impact of using topical and systemic medications as well as vitamin and food supplements on the total and hemispheric RBF and total venous cross-sectional area in normal patients and patients with glaucoma. The results showed that none of the topical and systemic medications and supplements used by the subjects in this study was associated with total or hemispheric RBF or total venous cross-sectional area (P > 0.05) in normal or glaucomatous eyes.

Table 4 demonstrates the associations between the RBF and RNFL and GCC thickness values and the RS in corresponding hemispheres and hemifields. The reduced RBF in the abnormal hemisphere was significantly associated with the thinner RNFL and GCC in the same hemisphere, but there was no significant association between these parameters in the normal hemisphere.

*One-way analysis of variance with Tukey–Kramer honestly significant difference post hoc test (JMP 8.0.2; SAS Inc., Cary, NC).

Fisher exact test.
One-way analysis of variance with Tukey honestly significant difference post hoc test (JMP 8.0.2).

We did not find any significant association between RBF and RS in either hemisphere and its controlling hemispheres.

In the glaucoma group, 15 eyes had perimetric abnormalities in the superior hemisphere and 15 eyes had abnormalities in the inferior hemisphere. Nine patients with glaucoma had arterial hypertension and 2 patients with glaucoma had controlled hypertension, and 2 patients with glaucoma had controlled hypertension. It is unclear whether the retinal vascular changes are primary or secondary in glaucoma. One plausible hypothesis refers to the fact that when the demand is diminished the supply is also reduced. Another hypothesis states that the loss of RGCs may affect regional oxygen demand, or the need of vascular supply in the corresponding superficial retinal area, which would trigger the retinal vascular adjustment by autoregulatory mechanisms. It has been shown that the retinal vascular contribution to the total parapapillary RNFL thickness may increase with glaucoma progression. A combined model of primary and secondary insults in glaucoma has been proposed by Cherecheanu et al. The primary insult appears to occur at the ONH, with increased IOP and ischemia affecting RGC axons at the post-laminar region. The biomechanical properties of the tissue and cerebrospinal fluid pressure would interact as the modulating factors, preparing the background for the secondary insults. The secondary insults may occur if the perfusion pressure decreases below the lower limit of autoregulation or neurovascular coupling fails. The vascular endothelial dysfunction and impaired astrocyte-vessel signaling also may be responsible at this stage. It has been proposed that the retinal vessels are not only under the control of the vascular endothelial cells but also under the control of the neural and glial cells. Autoregulation of ocular blood flow compensates for varying perfusion pressures, adapts to the retinal activity (neurovascular coupling), and maintains the posterior segment at a constant temperature. It has been hypothesized that if regulation does not occur according to the needs of the tissue, vascular dysregulation occurs. Patients with disturbed autoregulation tend to have unstable ocular blood flow, which in turn may provoke reperfusion injury, leading to oxidative stress and glaucomatous optic neuropathy. Using a mouse model of glaucoma, it has been shown that ischemia and reperfusion injury resulted in RGC death within 48 hours and degenerated capillaries within 1 week, indicating that capillary degeneration is an unrecognized component of acutely elevated IOP and develops only after neurodegeneration is severe. This finding raises the possibility that damage to the neural retina contributes to capillary degeneration, secondary to the RGC death. A relationship among retinal venous caliber, IOP, and cerebrospinal fluid pressure was recently noted, with the degree of retinal venous caliber being associated with the translaminar pressure gradient.

In this study, we observed that RBF, RNFL, and GCC were reduced in the normal hemisphere of glaucomatous eyes compared with the mean hemispheric values in the

GCC = ganglion cell complex; RBF = retinal blood flow; RNFL = retinal nerve fiber layer.

### Discussion

Several studies have demonstrated that vascular factors contribute to the development and progression of glaucomatous optic neuropathy. It has been shown that attenuation of retinal vessels is associated with structural loss in glaucoma, which could be independent of systemic vascular risk factors and IOP. It has been suggested that vascular factors are associated with the apoptosis of RGCs and development and progression of glaucomatous damage and that the mechanical compression of the microvasculature at the level of lamina cribrosa may affect the perfusion of the ONH, leading to RGC ischemia and apoptosis. Other studies have shown that retinal vessels might be involved in the pathogenesis of glaucoma.

It is unclear whether the retinal vascular changes are primary or secondary in glaucoma. One plausible hypothesis refers to the fact that when the demand is diminished the supply is also reduced. Another hypothesis states that the loss of RGCs may affect regional oxygen demand, or the need of vascular supply in the corresponding superficial retinal area, which would trigger the retinal vascular adjustment by autoregulatory mechanisms. It has been shown that the retinal vascular contribution to the total parapapillary RNFL thickness may increase with glaucoma progression. A combined model of primary and secondary insults in glaucoma has been proposed by Cherecheanu et al. The primary insult appears to occur at the ONH, with increased IOP and ischemia affecting RGC axons at the post-laminar region. The biomechanical properties of the tissue and cerebrospinal fluid pressure would interact as the modulating factors, preparing the background for the secondary insults. The secondary insults may occur if the perfusion pressure decreases below the lower limit of autoregulation or neurovascular coupling fails. The vascular endothelial dysfunction and impaired astrocyte-vessel signaling also may be responsible at this stage. It has been proposed that the retinal vessels are not only under the control of the vascular endothelial cells but also under the control of the neural and glial cells. Autoregulation of ocular blood flow compensates for varying perfusion pressures, adapts to the retinal activity (neurovascular coupling), and maintains the posterior segment at a constant temperature. It has been hypothesized that if regulation does not occur according to the needs of the tissue, vascular dysregulation occurs. Patients with disturbed autoregulation tend to have unstable ocular blood flow, which in turn may provoke reperfusion injury, leading to oxidative stress and glaucomatous optic neuropathy. Using a mouse model of glaucoma, it has been shown that ischemia and reperfusion injury resulted in RGC death within 48 hours and degenerated capillaries within 1 week, indicating that capillary degeneration is an unrecognized component of acutely elevated IOP and develops only after neurodegeneration is severe. This finding raises the possibility that damage to the neural retina contributes to capillary degeneration, secondary to the RGC death. A relationship among retinal venous caliber, IOP, and cerebrospinal fluid pressure was recently noted, with the degree of retinal venous caliber being associated with the translaminar pressure gradient.
normal eyes. There have been reports of reduced RBF in glaucoma\textsuperscript{12,13}, however, to the best of our knowledge, this is the first report of reduced RBF in the hemisphere with apparently normal visual field of glaucomatous eyes with single-hemifield damage. The finding of early structural loss in the hemisphere with apparently normal visual field is consistent with the literature that demonstrates that eyes with SAP defects confined to a single hemifield have evidence of diffuse attenuation in RNFL, macular thickness, and RS in apparently normal areas of the visual field.\textsuperscript{30–32}

In this study, the glaucoma group happened to have lower systemic blood pressure, which might be considered a limitation from the study design perspective. However, lower systemic blood pressure led to lower MOPP in the glaucoma group, who had reduced RBF. In our study, the blood velocity did not differ between the 2 groups significantly; however, the vessel caliber was significantly reduced in the glaucomatous eyes. The RBF is the product of retinal blood vessel cross-sectional area times blood velocity. Since the velocity did not differ between the 2 groups, the reduced RBF was presumably due to reduced retinal vessel caliber, as we observed. This finding is in agreement with previous studies that reported attenuation of retinal vessels in glaucoma.\textsuperscript{11,14} However, the association between glaucomatous progression and retinal vessel diameter is still controversial.\textsuperscript{33}

Our finding that RBF and vessel diameter were significantly reduced in glaucoma independent of the patient’s age agree with the findings of Jonas and colleagues, who found that the vessel diameters decreased significantly with increasing glaucoma stage independent of the patients’ age. It should be considered that open-angle glaucoma is an age-related disease; however, the rate of RNFL or GCC loss due to glaucoma may be faster and not proportional to the rate of aging in glaucoma subjects. In addition, there is a great chance that the RBF is compromised in glaucoma subjects because of factors other than glaucoma, such as atherosclerosis or other comorbidities; therefore, the association between RBF and glaucoma is not straightforward.

Aging impacts ocular blood flow through the change in vasculature tone and some degree of endothelial dysregulation, leading to an increase in systolic blood pressure that causes an increase in MOPP. The autoregulatory capability of the retinal vasculature in normal aging is the main determinant at this stage. If the glaucoma progression is accelerated compared with progressing age, the decreased RBF in glaucoma progression and in progressing aging will not be concordant. This question was not the intent of the this study, but it is an excellent hypothesis for further studies using a longitudinal study design.

The Blue Mountains Eye Study included 3654 participants and found that retinal arteriolar attenuation was associated with long-term risk of open-angle glaucoma and demonstrated that early vascular changes are involved in the pathogenesis of glaucoma. The Singapore Malay Eye Study, with 3019 participants, found a significant association between the attenuation of retinal arteriolar and the venular caliber changes with glaucomatous optic neuropathy, independent of IOP. Our findings agree with these large studies.

Various studies have shown associations between structural loss and retinal vascular change in glaucomatous eyes. Consistent with previous studies, the current study detected glaucomatous structural loss in the RNFL and GCC of glaucomatous eyes, significantly associated with the RBF in the hemisphere corresponding to the abnormal hemifield. There is evidence that the relationship between glaucomatous structure and function is highly complex and in part dependent on the severity of glaucoma. The relationship between structure and RBF is equally complex and may or may not be associated with one another. More studies are required to address this important question.

Of interest, our results demonstrate no relationship between RBF and RS in the corresponding abnormal hemispheres and hemifield. Previous studies have reported conflicting results with regard to an association between the RBF and the visual field abnormalities in patients with POAG. Some studies examined this association in the entire retina, and some in each hemifield separately, and yet none were able to report a significant association between RBF and glaucomatous field damage in patients with POAG. To examine the associations between RBF and function in the normal and abnormal hemispheres, we converted individual RS values of each visual field to the linear scale of 1/Lambert to circumvent the nonlinearity of the decibel scale. This conversion made all ranges of loss uniformly consistent across all stages of disease. Hwang et al converted all structural parameters and RBF measures to logarithmic scale of decibels and found a significant association between the RBF and the visual field mean deviation but inconsistent relationships between RBF and glaucomatous structural measures. Dissimilarities in the study population, stage of disease, local metabolic variables that regulate blood flow, and systemic factors, including blood pressure and antihypertensive therapy, may contribute to the observed differences between these 2 studies. The special value of the current hemispheric study compared with the global analysis of Hwang and colleagues is that our study rules out the effect of global confounders that act on both hemispheres, such as glaucoma medication, blood pressure medication, IOP, and blood pressure. It has been shown that attenuation of retinal vessels is associated with structural loss in glaucoma, which could be independent of systemic vascular risk factors and IOP. These findings emphasize the complex relationship between vascular physiologic mechanisms that regulate ocular blood flow and glaucomatous optic neuropathy. Longitudinal studies are necessary to further explore the relationship among impaired autoregulation, RGC survival, and visual function.

Several Doppler OCT methods have been used to measure the blood velocity for the calculation of RBF. Each method has its own strengths and shortcomings. One of these approaches calculates the angle between the scanning beam and the flow direction from structural OCT tomograms using registered 3-dimensional images. This method is not accurate for vessels that are close to perpendicular to the incident beam. In the second approach, the flow is measured directly from en face cross-sections, is not angle dependent, and leads to a direct value of the absolute flow. It requires a high-speed OCT platform, but even at high speed, the vessels within the volume are scanned consecutively and might exhibit different cardiac pulse phases. In the third approach, the 3-dimensional velocity vector is measured using simultaneous multi-beam illumination of the same sample point from different angles. This technique is complex but not ideal for retinal imaging. The sensitivity of each beam is reduced to decrease the total illumination power to the eye for laser safety considerations. The overlap of several beams on the retina, required for accurate velocity calculation, is challenging. The absolute velocity cannot be calculated if the incidence plane is perpendicular to the flow direction in the en face projection. In the fourth method, a flexible scanning dual beam bidirectional system is used. The system is based on high-speed swept source technology that allows the measurement of higher flow velocity closer to the ONH. The velocity is extracted independently of the vessel’s orientation and angle. This technique has limited precision because of the small angular separation between the 2 beams. In the last method, which was used in our study, the vessel angle is extracted from double circular scans at different scan radii. Using the dual scan beam helps with more accurate determination of the vessel angle. This method is sensitive to eye movement, but the motion artifact can be removed using proper 3-dimensional registration to provide a correct reference volume.
Study Limitations

We were able to measure only the total and hemispheric RBF in a group of mild to moderate glaucomatous eyes with single-hemifield damage, but we were not able to measure the localized RBF confined to areas smaller than the retinal hemisphere. This technology does not measure the microcirculation of the ONH and neuroretinal rim. The Doppler OCT blood flow measurements have been reported to have reasonably good reproducibility, with intraclass correlation coefficients of 0.93 for repeat measurements. The repeatability of total RBF, measured as the coefficient of variation, was 10.9% in the normal group and 14.3% in the diseased eyes with glaucoma, diabetic retinopathy, and branch retinal vein occlusion. The variability of this technology may still be improved. Doppler SD-OCT measures the retinal venous blood flow velocity but not arterial velocity because arterial velocity often exceeds the detection range of the device. However, since retinal circulation is a closed circulatory system, the total amount of flow in retinal veins is assumed to be equal to the total amount of flow in retinal arteries. One of the technical limitations of the study was the use of semiautomated grading and calculation technique for blood flow measurements. This method is tedious and time-consuming. Recent advancements are under way to circumvent the semiautomated technique to a fully automated method. Moreover, the role of a grader makes the calculations susceptible to the grader’s potential subjective errors.

The concomitant use of topical and systemic medications during the course of this study could affect the RBF. Few studies have examined the impact of systemic medications and supplements on RBF in patients with glaucoma with controversial results. Topical glaucoma medications reduce the IOP and may indirectly increase the MOPP. An increase in MOPP does not necessarily lead to an increase in RBF because the retinal circulation has autoregulatory mechanisms, unless the perfusion pressure falls below the lower limit of autoregulation or the neurovascular coupling fails.

Some reports have indicated that topical carbonic anhydrase inhibitors increase RBF in patients with glaucoma and improve retinal vascular autoregulation as the result of blockade of carbonic anhydrase and an increase in carbon dioxide concentration in local tissues, resulting in vascular dilation and increased blood flow. There is some evidence that shows some calcium channel blockers, adenosine, histamine, estrogens, and nitric oxide precursors, such as L-arginine, may increase ocular blood flow in general, and that alpha-2 adrenergic agonists may decrease the RBF. Overall, we did not find any significant association between total or hemispheric RBF and topical and systemic medications and dietary supplements used in this study, as demonstrated in Table 3, which may be due to the small sample size.

The impact of topical mydriatic agents on ocular hemodynamic parameters might be considered a confounding factor. We recently published an article regarding the impact of topical mydriatic ophthalmic solutions on retinal vascular reactivity and blood flow in normal eyes. We found that the 3 commonly used mydriatic agents did not differentially influence the RBF of the major retinal arterioles in normal eyes. In the current study, all subjects’ eyes were dilated using 1% tropicamide and 2.5% phenylephrine eye drops; therefore, the same dilating agent influenced ocular hemodynamics in all subjects similarly should it have any impact on the RBF. Moreover, because glaucoma is associated with autonomic and regulatory dysfunction, one cannot exclude the effect of dilating agents on the patients with glaucoma or an abnormal hemifield. Studying such an effect in the glaucoma population is the subject of another major experimental undertaking.

In conclusion, in glaucomatous eyes with single-hemifield damage, the RBF was reduced in the hemisphere corresponding to the abnormal hemifield, and the reduced RBF was associated with thinner RNFL and GCC thicknesses in the corresponding hemisphere. The RBF in the hemisphere with apparently normal visual field was reduced compared with the mean hemispheric flow values in the healthy eyes. These findings suggest that glaucoma is associated with vascular changes in the retina.
